Graphene is a single layer of carbon atoms densely packed in a honeycomb lattice with each carbon atom accommodating four valence electrons: one π electron and three σ electrons [1]. The lone unpaired π electron in the half-filled p\(_z\) orbital would form a π bond with the neighboring carbon atoms leading to delocalized π bands. Three σ electrons, sp\(^2\)-hybridized with neighboring three carbon atoms, form stronger σ bonds within the graphene layer. The π electrons play a predominant role in the electronic excitations below 10 eV while the σ electrons have important contributions at energies above 10 eV [1]. Furthermore, graphene is characterized by the signature linear dispersion of the π electrons near K, K’ points of the Brillouin zone (Dirac cone) [1].

Recently, the electronic excitations in monolayer graphene have been widely studied using electron energy loss spectroscopy (EELS) [2-3], which could be separated into three distinct spectral regime: the low-energy excitations at 0 ~ 3 eV [2], the spectral features at ~ 4.5 ~ 5 eV (π plasmon) and ~ 14.5 ~ 15 eV (π+σ plasmon) [3]. The low-energy excitations at 0 ~ 3 eV has been demonstrated with the characteristic square root of momentum (q) dependence of 2D plasmons [2], while the dispersion of π plasmon has been reported to exhibit either linear dependence [3] or quadratic dependence [4], in contrast to the square root of q dependence predicted by theoretical prediction in literature [5]. Furthermore, the π plasmon dispersion exhibits a classical in-plane anisotropy in the parent graphite, while that in monolayer graphene remains largely unexplored. Here, we report our studies to address the aforementioned issues concerning the π plasmon in monolayer graphene using momentum-resolved EELS (ω-q maps) with q spanning from 0 to Brillouin zone boundary (~1.5 Å\(^{-1}\)).

Figure 1(a) displays the momentum resolved ω-q maps in monolayer graphene along the ΓM direction with the momentum resolution of ~1.4×10\(^{-4}\) Å\(^{-1}\), clearly showing two spectral branches: a lower-energy branch with stronger intensity at ~ 4.5 eV and a higher-energy branch with much weaker intensity. Figure 1(b) shows the EELS spectra at different q values extracted and integrated with window of 0.002Å\(^{-1}\) and over the full q range (see the bottom gray curve). This integrated spectrum faithfully reflects the π and π+σ plasmons in monolayer graphene at 4.5 and 15 eV, respectively [3,4]. The individual q-dependent spectrum in Figure 1(b) reveals the respective dispersions of the two plasmon branches from 4 and ~13 eV at q → 0 (see also the enlarged inset). In addition, the initial spectral energy of 4 eV in monolayer graphene at q → 0 coincides with the energies of the well-known π → π* interband transitions in graphite [1]. In accordance with the further q-dependent experimental results to be described below (see Figure 2), we consider the spectral feature at 4(4.5) eV to be simply π plasmon mode in this study.

Figure 2(a) shows the momentum resolved ω-q maps extension of Figure 1(a) to the ΓM zone boundary and Figure 2(b) exhibits the corresponding q-dependent spectra derived at each individual q. It clearly reveals that the π (π+σ) plasmon disperses from 4 eV (~13 eV) to ~12 eV (~30 eV) at q= 1.4 Å\(^{-1}\), respectively. Furthermore, an additional spectral feature at 4.5 eV becomes visible from q ≥0.5 Å\(^{-1}\) and...
continuously disperses upward to ~7 eV at $q = 1.4 \text{ Å}^{-1}$. Moreover, this spectral feature exhibits a linear dispersion and an energy of ~ 4 eV when extrapolated to $q=0$, coinciding with the $\pi \rightarrow \pi^*$ interband transition in graphene [1]. It strongly suggests that this linearly dispersive feature is due to direct nonvertical interband transitions, giving rise to the in-plane anisotropy in monolayer graphene. This is the first experimental observation for the low-energy dispersive spectral feature in monolayer graphene, and has never been documented in literature.
